

# The Causal Effect of Regulations on Economic Growth: Evidence from the US States

Patrick A. McLaughlin      John T.H. Wong

Dec 6 2024, 10:59

## Abstract

We exploit variation in statehood recency across US states to estimate the effect of regulatory accumulation on economic growth. Regulatory levels are measured using QuantGov’s State RegData. The identification strategy is based on institutional sclerosis, the hypothesis that stable societies become stagnant over time as interest groups seek to impose restrictions on the economy, slowing its capacity to adapt to changing conditions. We find that a higher level of regulation’s exogenous component significantly reduces GDP growth.

## 1 Introduction

We typically think there is some tradeoff between regulation and efficiency. But until the past several years, the extent to which an economy is regulated, let alone regulation’s effect on economic growth, has been difficult to estimate. The two main issues constraining research in the literature had been, first, the absence of data that could directly capture the size and variation of regulations at each level of government. In contrast, this study leverages datasets that are generated from textual analysis programs and machine learning algorithms that quantify regulations at degrees of directness and scale not achieved by research in the past. The second issue had been that very few of the studies in the literature had identified an exogenous variation in regulatory levels, limiting their ability to infer a causal relationship. To that end, we draw on the institutional sclerosis hypothesis to justify the use of a given US state’s age as an instrumental variable. State age refers to the years since a US state’s most recent admission to the union. This allows us to obtain an exogenous component of regulatory accumulation.

We find that a higher level of regulation reduces the growth of GDP at the state level. Specifically, a 10 percent increase in regulatory restrictions is estimated to cause GDP to fall by 0.37 percentage point—about one-seventh of a typical state’s annual GDP growth. This implies that moving across the interquartile range in restriction count (i.e., reducing regulatory restrictions by 42 percent) would increase aggregate GDP by 1.54 percentage points.

Broadly defined, regulations are mandates that limit the domain of permissible actions of economic actors, ostensibly designed and implemented to achieve some specific outcome(s).

One view of regulation is that it is a policy vehicle for addressing market failures (such as externalities and information asymmetries) and maximizing social welfare. However, regulation can increase costs and subject potential entrants to barriers of entry. Opponents of regulations note that they entail compliance cost and can invite attempts to capture transfers, which redirect factors from their more productive uses.<sup>1</sup> George Stigler, for example, hypothesized that regulation is captured by industry and that it is by producers' monopolistic design intended to restrict output.<sup>2</sup>

Mancur Olson has argued that on top of individual regulations, the phenomenon of *regulatory accumulation* can exacerbate the aforementioned costs of regulation. When barriers to entry are ubiquitous, they can in general slow the rate at which resources are reallocated to more profitable sectors that spring up in response to technological change.<sup>3</sup> Regulatory complexity increases the size of government required to enforce said rules, encourages allocation of legal resources to discover loopholes, creates specialists who lobby against simplification, and spawns further regulations (Olson 1984, 73-4). On a similar note, regulatory accumulation increases the likelihood of contradiction (or what Hillel Steiner would term "impossibility"), which can lead to indeterminate evaluations of the legality of actions. Ambiguous laws require judicial interpretation, in turn creating rules that are more ad hoc and potentially more arbitrary.<sup>4</sup>

The significance and magnitude of Olson's hypothesis have been tested in the past, starting with evidence that Olson compiled with Kwang Choi. Olson and Choi found that a state's founding year (i.e., the additive inverse of state age) is significantly predictive of declines in both aggregate and per capita income growth at the US state level between 1965-78 and between 1946-78. This result is particularly noteworthy, given that most US states were founded at least a century before the period for which income was measured (Olson 1984, 104-6; 114). Furthermore, state age is positively and significantly correlated with one measure of interest group accumulation, specifically union membership as a percentage of employees (non-agricultural) (Olson 1984, 107-8).

Subsequent scholars have also found evidence to reinforce the process of institutional sclerosis posited here. In a meta-analysis, Jac Heckelman found that subsequent researchers generally concurred with Olson's findings. The proportion of statistical studies ( $n = 28$ ) which offer support, mixed support, and no support to institutional sclerosis respectively are 57 percent, 18 percent, and 25 percent<sup>5</sup>—though it should be cautioned that the sample provides only correlational evidence. Among studies which focused on US states and the role of interest groups, Richard Vedder and Lowell Gallaway found that state age and union membership are significantly and negatively correlated with per capita income growth.<sup>6</sup> Mark Crain and Katherine Lee estimated a significantly negative relationship between the same outcome and

business associations’ revenue as a share of income.<sup>7</sup>

This paper also contributes to the regulatory literature. John Dawson and John Seater made one of the first attempts to directly measure the quantity of regulations.<sup>8</sup> Prior to Dawson and Seater, most studies resorted to using indices of regulatory severity (either self-constructed or by organizations such as the OECD),<sup>9</sup> which can limit the scope of regulation evaluated (to only e.g., licensing requirements, product safety requirements, or employee health and safety) or the number of industries considered, in addition to introducing measurement errors. Dawson and Seater captured the growth of the Code of Federal Regulations by using page counts, creating a single time series of regulatory accumulation for federal regulations. Running simulations with an endogenous growth model, the authors estimated that if the pages of regulations had been unchanged since 1949, the economy would have grown 2.2 percentage points more annually—or an increase of \$38.8 trillion to GDP by 2011 (Dawson and Seater 2013, 160).

In one of the first applications of RegData, Bailey and Thomas (2017) investigate the effect of regulation as a potential “cost” to the economy by examining three metrics of entrepreneurship: firm births, firm deaths, and new hires.<sup>10</sup> (RegData will be described in more detail in Section 3.) The study also examines whether varying levels of regulation affects these entrepreneurship outcomes differently for small firms than for large firms. Overall, they find a small but statistically significant negative relationship between regulation and entrepreneurship, with some of the effects more pronounced for small firms compared to large firms.

Coffey et al. (2020) meanwhile, built upon the initial Dawson and Seater approach. Using industry-specific regulatory data from RegData, Coffey et al.<sup>11</sup> specified an endogenous growth model where growth depends on lagged knowledge investment and its interaction with regulation, and where knowledge investment depends on past growth and regulation. Exploiting variation in the level of regulation across industries and over time, they found that the economy would have grown 0.8 percentage points more annually if federal regulation remained at 1980 levels—or a \$4 trillion increase to GDP by 2012 (Coffey et al. 2020, 14-5).

More recently, Coffey and McLaughlin (2021) studied the case of regulatory budgeting in British Columbia, Canada, which reduced its count of regulations by just over one-third in three years.<sup>12</sup> The authors found that a 10 percent increase in regulatory stringency (i.e., a restriction count weighted by industry relevance) is associated with a 0.25 percentage point decrease in GDP per capita (Coffey and McLaughlin 2021, 36). There was additional causal

evidence from a difference-in-difference synthetic control setup which found that the reform (of reducing regulations by one-third) increased growth by 1.4 percentage points (Coffey and McLaughlin 2021, 35). However, the latter is estimated with a difference-in-difference setup that, although it did exploit a natural experiment and a synthetic control, ultimately relied on variation in levels of regulation across province and time and the assumptions required of difference-in-differences estimation (e.g., parallel trends and no confounding events). This illustrates the difficulty of designing a study where the shift in regulatory stringency is exogenous and where this shift can be measured with RegData. To this end, we introduce the concept of institutional sclerosis, which we argue provides a source of exogenous variation in regulation.

Coffey and McLaughlin (2021) makes important points not only about the potential growth effects of regulatory accumulation or red tape reduction, but also about the possibility that regulations do not have to correlate with population or the amount of economic activity in a given jurisdiction. Other research has demonstrated a fairly robust correlation between state population and the quantity of regulation (Bailey et al, 2021) and between industry size and the quantity of federal and state regulation (Law and McLaughlin, 2022).<sup>13</sup> Coffey and McLaughlin (2021) as well as Jones and McLaughlin (2022) present the counterargument that such correlations are not an obligatory byproduct of economic growth, but instead a result of inattention to regulatory accumulation by policymakers.<sup>14</sup>

The paper proceeds as follows. In Section 2, we describe the main model being estimated and justify the use of various variables. Section 3 describes the datasets on which this study relies. The results are shown in Section 4. Section 5 covers various robustness tests conducted in response to possible concerns about the model. Section 6 concludes.

## 2 A Model for Sclerosis

Mancur Olson (1984) offered the institutional sclerosis hypothesis to explain why affluent societies become stagnant with time. The main components of his hypothesis are as follows (76):

1. Stable societies with unchanged boundaries tend to accumulate more collusions and organizations for collective action over time.
2. On balance, special-interest organizations and collusions reduce efficiency and aggregate income in the societies in which they operate and make political life more divisive.
3. Distributional coalitions slow down a society’s capacity to adopt new technologies and to reallocate resources in response to changing conditions, and thereby reduce the rate of economic growth.

<sup>14</sup>Laura Jones and Patrick A. McLaughlin, ‘Measurement Options for Regulatory Budgeting’, *Harvard Journal of Law & Public Policy* Per Curiam 1 (2022): 43-60.

We formalize the first hypothesis by modeling restrictions as a function of state age:

$$R_{it} = e^{\theta_0 + \theta_1(t - T_i) + \vec{w}_i \vec{\delta} + \eta_{it}}.$$

- $t$  denotes current period and  $T_i$  is the period where stability initiates for state  $i$ , i.e., the period in which a state  $i$  joins the United States.  $t - T_i$ , then, is state age.
- $\theta_0$  is a scalar which adjusts the “inflection point” at which restrictions begin to accumulate. The higher its value, the sooner this point is.
- $\theta_1$  is a scalar which adjusts the slope of the  $R_t$  with respect to time.
- $\vec{w}_i$  is a vector of time-invariant observable determinants of regulation, which are scaled by  $\vec{\delta}$ .
- $\eta_{it}$  is an iid normal error term.

This restrictions function implies that:

$$\ln R_{it} = \theta_0 + \theta_1(t - T_i) + \vec{w}_i \vec{\delta} + \eta_{it}, \quad (1)$$

which provides us with the first-stage equation for estimating restrictions on state age.

This corresponds to a linear second-stage equation of output growth on the exogenous component of  $\ln R_{it}$ :

$$\frac{dY_{it}/dt}{Y_{it}} = \alpha_0 + \alpha_1 \ln R_{it-2} + \vec{w} \vec{\delta} + u_{it}. \quad (2)$$

- $Y_{it}$  denotes output at time  $t$  for state  $i$ .
- $R_{t-2}$  is the level of restrictions two periods (i.e., years) before period  $t$ . The lag is meant to reflect that regulatory accumulation, insofar as it has any effect, requires time to permeate into economic activity.
- $u_{it}$  contains a vector of  $K$  unobserved covariates that are correlated with  $\ln R_{t-2}$  and an iid normal error, i.e.,

$$u_{it} \equiv \sum_{k=1}^K v_{kit} \delta_k + \epsilon_{it}. \quad (3)$$

Note that this formalizes Olson’s third hypothesis, which suggests that  $\alpha_1 < 0$ . Before we proceed, we want to evaluate the model implicitly assumed by Equation 2. We do so by substituting Equation 1 into Equation 2:

$$\begin{aligned} \frac{dY_{it}/dt}{Y_{it}} &= \alpha_0 + \alpha_1 [\theta_0 + \theta_1(t - T_i - 2) + \vec{w}_i \vec{\delta} + \eta_{it}] + \vec{w} \vec{\delta} + u_{it} \\ &= \alpha_1 \theta_1 t + \alpha_0 + \alpha_1 \theta_0 - \alpha_1 \theta_1 (T_i + 2) + (\alpha_1 + 1) \vec{w}_i \vec{\delta} + \alpha_1 \eta_{it} + u_{it}. \end{aligned}$$

This provides us with a closed-form function of time on the right-hand side that we can integrate with respect to  $dt$ :

$$\begin{aligned}
\int \frac{1}{Y_{it}} dY_{it} &= \int \alpha_1 \theta_1 t + \alpha_0 + \alpha_1 \theta_0 - \alpha_1 \theta_1 (T_i + 2) + (\alpha_1 + 1) \vec{w}_i \vec{\delta} + \alpha_1 \eta_{it} + u_{it} dt \\
\Rightarrow \ln Y_{it} + c_1 &= t^2 \frac{\alpha_1 \theta_1}{2} + t[\alpha_0 + \alpha_1 \theta_0 - \alpha_1 \theta_1 (T_i + 2) + (\alpha_1 + 1) \vec{w}_i \vec{\delta}] \\
&\quad + t(\alpha_1 \eta_{it} + u_{it}) + c_2 \\
\Rightarrow Y_{it} &= Y_0 \underbrace{e^{t^2 \frac{\alpha_1 \theta_1}{2} + t[\alpha_0 + \alpha_1 \theta_0 - \alpha_1 \theta_1 (T_i + 2) + (\alpha_1 + 1) \vec{w}_i \vec{\delta}]}}_{f(t, T_i, \vec{w}_i)} e^{(\alpha_1 \eta_{it} + u_{it})t}.
\end{aligned} \tag{4}$$

where  $Y_0 \equiv e^{c_2 - c_1}$ . The output function implied by the second-stage equation is a standard exponential growth model with a base constant  $Y_0$ .

Plugging Equation 3 into Equation 4:

$$Y_0 \cdot e^{(\sum_{k=1}^K v_{kit} \delta_k)t} \cdot f(t, T_i, \vec{w}_i) \cdot e^{(\alpha_1 \eta_{it} + \epsilon_{it})t},$$

If we assume that  $Y_0$  is a Cobb-Douglas function of  $K$  initial factors of production ( $V_{10}, V_{20}, \dots, V_{K0}$ ) common to all states:

$$\begin{aligned}
Y_0 &= \prod_{i=k} V_{k0} \\
\Rightarrow Y_0 e^{\sum_{k=1}^K v_{kit} \delta_k} &= \underbrace{V_{10} e^{v_{1it} \delta_1 t}}_{V_{1it}} \times \dots \times \underbrace{V_{K0} e^{v_{Kit} \delta_K t}}_{V_{Kit}},
\end{aligned}$$

which are just standard forms assumed for time-variant factors of production. Under these assumptions about the constant of integration, each  $v_{kit} \delta_k$  is the state  $i$ 's time-variant continuous-compounding growth rate for factor  $k$ , i.e., the factor's average growth rate in state  $i$ .

If the assumptions about the constant of integration holds, we can interpret the 2SLS exogeneity condition as:

$$\text{Cov}(T_i | \vec{w}_i, v_{kit}) = 0, \text{ for all } k\text{-th factor parameters.}$$

i.e., that the period of admission for state  $i$ , given time-invariant determinants of admission, is uncorrelated with the average growth rate of typical factors of production, such as capital, in that state.

### 3 Data

Table 1 reports summary statistics.

Table 1: Summary Statistics

Characteristic	N = 77

---

$R_{it}$  is measured as the restriction count of a given state  $i$  in year  $t$ . A measure of state-level regulations is provided by QuantGov’s State RegData 2023.<sup>15</sup> RegData measures the *count* of *restrictions* in each state’s regulatory codes *and* statutes, at the document level. Not every line of regulation constitutes a restriction. Instead, each occurrence of one of five specific restrictive phrases—namely ‘shall’, ‘must’, ‘may not’, ‘required’, ‘prohibited’—counts as one restriction. We aggregate restrictions at the state level, creating a sample of 77 observations for our main specification. This provides us with a snapshot of most states’ restrictions within each year, from 2021 to 2023. The count of regulatory restrictions vary widely across states, with a mean of 276,130 and values ranging between 98,015 and 889,795.

We measure  $Y_i$  as the chained real GDP of a given state  $i$ .<sup>16</sup> The series is pulled from the US Bureau of Economic Analysis’s National Income and Product Accounts (BEA-NIPA).<sup>17</sup> We are more interested in the growth of GDP than that of per capita GDP. This is because even if regulation affects efficiency and raises per-capita income growth, this increase may eventually dissipate as net migration to the state increases. Aggregate GDP growth is intended to capture both per-capita income and population dynamics.

<sup>15</sup>Patrick A. McLaughlin, Michael Gilbert, Jonathan Nelson, and Thurston Powers, ‘State RegData 2023 (dataset)’, QuantGov, Mercatus Center at George Mason University (2023).

<sup>16</sup>In alternative specifications, we explored using personal income as the dependent variable and reached qualitatively similar results. However, those analyses did not correct for regional purchasing parities, which other researchers show to have dramatic effect on the bottom ten percent of income distributions across regions. For more, see Vincent Geloso and Younes Msaïd, ‘Adjusting inequalities for regional price parities: Importance and implications’, *Journal of Regional Analysis & Policy* 48 (2018): 1-8; and J. T. Callais and J. B. Pavlik, ‘Does economic freedom lighten the blow? Evidence from the Great Recession in the United States’, *Economics of Governance* 24 (2023): 357-398. Since our main focus is GDP growth, we leave exploration of income effects to future research.

<sup>17</sup>U.S. Bureau of Economic Analysis, ‘Table. SQGDP9 Real GDP in chained dollars’, BEA Data API (accessed September 2, 2024).

Our data is an unbalanced panel, including one year of observations for 19 states and two years of observations for 29 states. Figure 1 shows the number of times each state appears in our sample.

Figure 1: Number of Observations in Main Sample, by State

$T_i$  is the admission year of state  $i$  to the United States, with the exception of Southern states, where the variable is defined as years since their re-admission to the US in 1868, as the Civil War (in addition to reconstruction) likely disrupted or inhibited the development of interest groups (Olson 1984, 98).

Before we proceed, we should note that in addition to being structurally motivated, state age is a very plausible instrument for regulatory restrictions. First, it is difficult to conceive how state age, other than through the channel of institutional sclerosis, can affect present economic growth.

Second, we control for these potential determinants of statehood and we will show below that neither covariates are significant in either the first or second stage.  $\vec{w}_i$  is a vector of controls of a given state  $i$ . The vector includes a state's population recorded on the decennial census subsequent to statehood. This is because early population could have been driven by early industrial activity that has some persistent effect on current growth. In addition, territories seeking statehood had to meet population requirements (though they may not necessarily be set at a level that is binding).

We also include the geographical area of a state at admission. The concern there is that longer travel distances within a state can increase the cost to organize, which in turn can affect our endogenous variable. Both admission dates and state' early characteristics are provided by the US Census Bureau's Historical Statistics of the United States (HSUS).<sup>18</sup>

<sup>18</sup>Susan B. Carter, Scott Sigmund Gartner, Michael R. Haines, Alan L. Olmstead, Richard

Figure 2: Histogram of State Age

The final way we provide evidence for exogeneity is through overidentifying the 2SLS model, so as to conduct a J-test for instrument exogeneity. Relying on the same sclerosis hypothesis, we identify year of initial constitution and Euclidean distance to D.C. as additional instruments.<sup>19</sup> As we will show below as well, the hypothesis that instruments are exogenous cannot be rejected.

## 4 Results

The 2SLS results are reported in Table 2. Column 1 reports the results from a simple OLS regression of the outcome on log of restriction count. Consistent with the motivation for our identification strategy, log of restriction count as a predictor is not statistically significant.

Table 2: Estimating GDP Growth on Restrictions, OLS vs 2SLS with State Age

Moving onto the 2SLS first-stage results in Column 2, we see that state age is significant at the one percent level as a predictor for log of restriction count—which offers support to state age being a relevant instrument. Column 4 estimates a first-stage equation with controls for state age. Population around the time of admission nor geographical area have significance—assuaging concerns about the endogeneity of state age.

In line with expectations, older states experience higher levels of restrictions. This is illustrated in as Figure 3. The color of each observation is mapped to economic growth from  $t - 1$  to  $t$  (whereas restriction count is that from  $t - 2$ ; lighter indicates higher growth). It is immediately observable that states admitted more recently, in addition to having less restrictions, tend to exhibit higher growth today.

The second-stage results—Column 3—are encouraging as well. The exogenous component of treatment is statistically significant at the five percent level. A higher level of regulation reduces real GDP growth. The significance level holds, and magnitude increases, when controls are added (Column 5). The magnitude of the coefficient is 19-times larger than that in Column 1, consistent with our suspicion that a simple OLS estimation captures upward bias. The estimate from Column 5 implies that a 10 percent increase in restrictions will change GDP by  $\beta \cdot \frac{dReg}{Reg} = -0.365$  percentage point. This is rather significant as states' GDP on average grew 2.39 percent, which would make our estimate about one-seventh of yearly growth. For an alternative interpretation: moving across the interquartile range in restriction count (i.e., reducing restrictions by 41.64 percent, or -131,441 restrictions) would increase real GDP by 1.52 percentage points.

The F-statistic is above 10 under the parsimonious specification (Column 2), but it falls below 10 as controls are added (Column 4). To address concerns about the instrument's relevance, we run the Anderson-Rubin test for 2SLS models, which is designed to perform inference on the treatment's coefficient in the presence of a weak instrument. The test statistic is statistically different from zero ( $p = 0.0011$ ). The 95 percent confidence interval

Figure 3: Log-Scale Restrictions vs. State Age with Color Gradient Representing Present GDP Growth

for the estimated coefficient is  $[-0.1148, -0.0128]$ . This puts even the weaker end of the interval below zero, confirming our exogenous component of regulation as a significant and relevant predictor.

## 5 Robustness

### 5.1 Stage Age Specification

In this section, we discuss results obtained under alternative specifications of state age, shown in Table 3. Generally, the results are robust. Columns 1 and 2 respectively show the first- and second-stage results when year fixed effects are included. The motivation here is that state age ( $t - T_i$ ) is a linear equation of time. While we did not explicitly impose any structure on the error term  $\eta_{it}$  with respect to  $\eta_{it-1}$ , state age would correlate with the errors in the case where they are autoregressive. Only one factor is added since  $t = 2023, 2024$ . While the magnitude falls in the first-stage, second-stage results are essentially indistinguishable for Table 2 Column 5. Following the same motivation, results in Columns 3 and 4 are estimated with  $T_i$  as an instrument. Since  $T_i$  is time-invariant, the first-stage predictions becomes a within-state mean of  $\ln R_t$ . Either specifications produce the same result.

Skepticism has often been raised, particularly during peer review and academic presentations, about Olson's definition of state age for Southern states. For this reason, we define a second variant of state age that is equivalent to  $t - \tilde{T}$ , where  $\tilde{T}$  is the period when a state

enters the United States for the first time. This specification essentially assumes that the Civil War did not interrupt interest group formation. Columns 5 and 6 show that our model from Table 2 is robust to this alternative definition of state age, with coefficient estimates for state age and log of restriction count being almost unchanged from Table 2.

	$\ln R_{t-2}$	$\% \Delta \text{GDP}$	$\ln R_{t-2}$	$\% \Delta \text{GDP}$	$\ln R_{t-2}$	$\% \Delta \text{GDP}$

## 5.2 Overidentification

To offer evidence on instrument exogeneity, we now conduct a J-test by overidentifying the first-stage equation, i.e., by including more instruments than endogenous variables. In an overidentified model, not all instruments can be perfectly correlated with the endogenous variables (and thus the second-stage residuals). This in turn allows us to test whether 2nd-stage residuals are correlated with our instruments.

We turn to two additional instruments. The first is the year in which a given state's first constitution was ratified (or "year of initial constitution"), collected by Julia Clouse (2019). The reasoning behind using year of initial constitution is similar to that of state age: a constitution provides a framework for stability that makes organizing, capture, and sclerosis possible. 27 states saw the establishment of a constitution prior to statehood. The series is therefore largely independent from state age (this is particularly true for Southern states, which by our definition are much younger).

The second is the Euclidean distance between a state's coordinates and that of D.C. in the latitude-longitude space. This measure gives us an approximation of a state's distance from

D.C. The two key ideas here are that the interaction between where a state ends up located and D.C.'s location is as good as random, but that once both are established, nearness to D.C. implies more organizing activity that in turn promotes statehood and sclerosis down the road.

Table 4 shows the results. The J-test is implemented by running the 2nd-stage residuals (from an overidentified 2SLS estimation) onto the same set of instruments and control variables. Note that the null hypothesis is that the instruments are jointly exogenous. Thus, a significant j-statistic indicates that the IVs are correlated with disturbances in the outcome. Column 1 uses both state age and year of initial constitution as instruments, while Column 2 uses all three variables. While the J-statistic in the latter case does increase in significance, the null cannot be rejected under either overidentified specifications at even the ten percent level. This suggests the main instrument is in fact exogenous.

	2nd-Stage Residuals	
	Two IVs	Three IVs
State Age	−0.0000 (0.0001)	−0.0000 (0.0001)
Year of Initial Constitution	−0.0000 (0.0001)	−0.0001 (0.0001)
Euclidean Distance from D.C.		0.0003 (0.0003)
Intercept	0.0806 (0.2120)	0.1926 (0.2131)
J-statistic	0.1473	2.0713
P-value	0.7011 (df = 1)	0.1501 (df = 2)
Controls	YES	YES
R <sup>2</sup>	0.0020	0.0283
Num. obs.	77	77

P-value indicates the probability that the null (that instruments are exogenous) is true.

Table 4: Overidentifying Restrictions Test (J-Test)

### 5.3 Different Lag Specifications

In our main model, we lag restriction count by two periods. We now test other lag specifications. Table 5 shows the 2SLS 2nd stage results when different lags are used. Three results are worth highlighting. First, the Lag-1 specification is just as significant as our baseline specification (Lag-2). Second, the Lag-0 specification, which can be thought of as a placebo measure of regulation, since regulation at  $t$  might have little to no overlap with economic activity from  $t - 1$  to  $t$ . As expected, its exogenous component is not a significant predictor of growth. Finally, including restriction levels from two years leads both to become insignificant predictors (Columns 4, 5). This is not surprising, as restriction levels, between-years and within-state, should be highly collinear.

	%ΔGDP				
	Lag-2	Lag-1	Lag-0	Lag-1,2	Lag-0,1
$R_t$			-0.0125 (0.0138)		-1.3588 (1.9174)
$R_{t-1}$		-0.0265* (0.0120)		-0.4401 (1.2626)	1.3323 (1.9165)
$R_{t-2}$	-0.0365* (0.0166)			0.4046 (1.2620)	
Intercept	0.4761* (0.2064)	0.3514* (0.1495)	0.1764 (0.1722)	0.4648* (0.2207)	0.3509 (0.3351)
Controls	YES	YES	YES	YES	YES
Second IV?	NO	NO	NO	YES	YES
Num. obs.	77	125	125	77	77

\*\*\* $p < 0.001$ ; \*\* $p < 0.01$ ; \* $p < 0.05$

## 5.4 Transforming Regulation to Linear or Squared

In Section 2, we formally demonstrated that specifying  $\ln R_{t-2}$  as the endogenous variable is structurally consistent with a Cobb-Douglas production function. While we maintain this structural foundation, we explore alternative specifications by running our baseline model with the treatment defined as either the restriction count in levels ( $R_{t-2}$ ) or its square ( $R_{t-2}^2$ ).

Table 6 presents the 2SLS second-stage results. Column 1 shows the baseline estimate, while Columns 2 and 3 confirm that the significance of our results is robust to these alternative transformations of the restriction count. Interestingly, the exogenous component of the squared restriction count is statistically more significant than that of the baseline log-transformation. Nevertheless, as both alternative specifications yield lower F-statistics, we continue to prefer the baseline log-transformation, where state age proves to be a more relevant instrument.

	%ΔGDP		
$\ln R_{t-2}$	-0.0365*		
	(0.0166)		
$R_{t-2}$ (Millions)		-0.1255*	
		(0.0615)	
$R_{t-2}^2$ (Trillions)			-0.1751**
			(0.0550)
Intercept	0.4761*	0.0549**	0.0355***
	(0.2064)	(0.0167)	(0.0052)
1st Stage F-statistic	4.4811	2.7274	1.7066
Controls	YES	YES	YES
Num. obs.	77	77	77

\*\*\* $p < 0.001$ ; \*\* $p < 0.01$ ; \* $p < 0.05$

Table 6: Estimating GDP Growth on Varying Specifications of Restrictions, 2SLS

## 5.5 Geography as Placebo Instrument

We would like to consider one final objection, which is that state age is simply proxying for region-based growth in Western or Southern states. What the results indicate then in fact is not institutional sclerosis, but some spurious correlation between region, regulation, and growth. If this is true, we might see even stronger results when we directly use geography as a “placebo” instrument. As Table 7 shows however, this is not the case. Log of restriction count as a treatment loses significance when we use latitude or longitude (or both) as instruments. In other words, state age meaningfully captures variation that cannot be explained through the region to which a state belongs.

	%ΔGDP		
	Longitude	Latitude	Longitude + Latitude
$\ln R_{t-2}$	-0.0468	0.0167	0.0015
	(0.0435)	(0.0170)	(0.0117)
Population at Admission	0.0209	-0.0045	0.0016
	(0.0252)	(0.0155)	(0.0124)
Area Size	-0.0279	0.0062	-0.0020
	(0.0371)	(0.0237)	(0.0192)
Intercept	0.6306	-0.1586	0.0298
	(0.5405)	(0.2111)	(0.1459)
Controls	YES	YES	YES

## 6 Conclusion

This paper has presented evidence on how regulatory accumulation affects economic growth by using state age as an instrument that affects regulatory accumulation only through institutional sclerosis. To justify the instrument’s validity, we leveraged Mancur Olson’s hypothesis of institutional sclerosis and further offered evidence that state age is in fact a relevant and exogenous instrument. Our main results indicate that a 10 percent increase in state level regulatory restrictions will reduce real GDP by 0.365 percentage point. Results are robust to controlling for potential determinants of statehood and alternative specifications of treatment variables. Robustness tests also indicate that the results are not driven by spurious correlation with geography. Our findings suggest that reducing the aggregate number of regulations at the state level can promote faster economic growth – a finding that is consistent with Coffey and McLaughlin (2021), Coffey et al. (2020), and Dawson and Seater (2014), but represents the first to find this result at the state level in the United States.

We should acknowledge that the accumulation of regulation does not always equate to an increase in stringency. Though RegData allows one to construct indices of regulatory stringency based on industry relevance, this can introduce considerable noise to the measure of regulatory variation. One workaround can be drawn from McLaughlin and Sherouse’s (2016) and McLaughlin and Warlick (2020) Federal Regulation and State Enterprise Index, which aggregates industry restrictions from federal regulations to the state level using a weighted rather than simple sum, where weights are a given industry’s contribution to a given state’s output.<sup>20</sup> Future research should explore new measures of stringency that even better approximates a jurisdiction’s level of regulation, while distinguishing between different types of regulations.
